Probabilistic Shaped Multilevel Polar Coding for Wiretap Channel

Li Shen, Yongpeng Wu, Senior Member, IEEE, Peihong Yuan, Member, IEEE, Chengshan Xiao, Fellow, IEEE, Xiang-Gen Xia, Fellow, IEEE, and Wenjun Zhang, Fellow, IEEE

Abstract—A wiretap channel is served as the fundamental model of physical layer security techniques, where the secrecy capacity of the Gaussian wiretap channel is proven to be achieved by Gaussian input. However, there remains a gap between the Gaussian secrecy capacity and the secrecy rate with conventional uniformly distributed discrete constellation input, e.g. amplitude shift keying (ASK) and quadrature amplitude modulation (QAM). In this paper, we propose a probabilistic shaped multilevel polar coding scheme to bridge the gap. Specifically, the input distribution optimization problem for maximizing the secrecy rate with ASK/QAM input is solved. Numerical results show that the resulting sub-optimal solution can still approach the Gaussian secrecy capacity. Then, we investigate the polarization of multilevel polar codes for the asymmetric discrete memoryless wiretap channel, and thus propose a multilevel polar coding scheme integration with probabilistic shaping. It is proved that the scheme can achieve the secrecy capacity of the Gaussian wiretap channel with discrete constellation input, and satisfies the reliability condition and weak security condition. A securityoriented polar code construction method to natively satisfies the leakage-based security condition is also investigated. Simulation results show that the proposed scheme achieves more efficient and secure transmission than the uniform constellation input case over both the Gaussian wiretap channel and the Rayleigh fading wiretap channel.

Index Terms—Physical layer security, asymmetric wiretap channels, multilevel coding, polar codes, probabilistic shaping.

I. INTRODUCTION

S a complement or an alternative to classical cryptographic techniques, the physical layer security (PLS) techniques provide an additional layer of security for future wireless communication networks by exploiting the inherent randomness of wireless channels [1]. The wiretap channel model was first proposed by Wyner [2] in 1975 and has become the fundamental scenario in PLS researches. Wyner

showed that a secure transmission with positive rate is possible by applying appropriate coding and signal processing scheme, and derived the secrecy capacity of the discrete memoryless wiretap channel (DMWC). In [3], the authors extended the concept of secrecy capacity to the Gaussian wiretap channel, and proved that the secrecy capacity is achieved by the Gaussian codebook. Under finite complex constellation input constraints, the secrecy capacity of the Gaussian wiretap channel was also studied in [4]. Moreover, the secrecy capacity of the fading wiretap channel has been considered [5], [6].

In addition to the information theoretic research on secrecy capacity introduced above, some practical wiretap codes are required to guarantee secure communication. The work in [7] presented a wiretap coding scheme based on low-density parity-check (LDPC) codes and shown that it achieves secrecy capacity in some cases. In [8], the authors proposed a secrecy capacity achieving polar coding scheme for the binary-input symmetric DMWC and proved that the scheme satisfies the reliability condition and the weak security condition. To avoid the measure of information theoretic secrecy metric like the security condition, a bit error rate (BER) based secrecy metric named security gap was suggested in [9] and has become one of the criteria for wiretap code design [9]–[13]. The secrecy metrics for fading wiretap channel were investigated in [14]. Moreover, with the popularity of artificial intelligence technologies in recent years, the wiretap code design via autoencoder has attracted the attention of researchers [15], [16]. Furthermore, to achieve a higher transmission rate, it is necessary to use a high-order discrete modulation. For instance, [17] optimized bit-labeling of bit-interleaved coded modulation (BICM) systems for the Gaussian wiretap channel, and [18] proposed a multilevel coding (MLC) scheme based on the punctured LDPC codes for physical layer security.

Nevertheless, for the Gaussian wiretap channel with standard uniformly distributed constellation input, such as conventional amplitude shift keying (ASK) constellations and quadrature amplitude modulation (QAM) constellations, there remains a gap between the achievable secrecy rate and the Gaussian secrecy capacity [4], and none of the existing works have considered bridging the gap.

Inspired by constellation shaping techniques, such as geometric shaping (GS) and probabilistic shaping (PS), which are commonly performed in point-to-point communication systems to achieve a Gaussian-like input distribution, we

may leverage constellation shaping to narrow the gap. The GS designs non-equidistant constellations with uniformly distributed constellation points, e.g., constellations for ATSC 3.0 [19], but their performance is worse than PS under the same modulation order [20]. The PS, on the other hand, generates constellation points from a standard constellation with nonuniform probability, e.g., trellis shaping [21], shell mapping [22], probabilistic amplitude shaping (PAS) [23] and Honda-Yamamoto (HY) scheme [24]. Particularly, PAS and the HY scheme can implement PS with lower complexity and more flexible transmission rate. The PAS scheme concatenates a distribution matcher (DM) with a systematic forward error correction (FEC) code to perform PS and channel coding [23], and is proved to achieve the capacity of additive white Gaussian noise (AWGN) channel [25]. Alternatively, [24] revealed the polarization of polar codes for the binary-input asymmetric discrete memoryless channel (DMC)¹ and thus proposed a polar coding scheme to achieve the asymmetric capacity. With HY scheme, the PS and FEC can be jointly implemented by just performing a polar decoder. Furthermore, the HY scheme has been extended to higher-order modulations by using the MLC structure [26], [27].

However, it does not mean that constellation shaping can be directly applied for transmission over the Gaussian wiretap channel, since achieving the secrecy capacity not only requires an optimal input distribution, but also implies that the amount of information leaked to the eavesdropper should tend to zero. More specifically, although a desired distribution can be achieved through constellation shaping, many wiretap codes, like [9]–[13], [17], [18], are designed merely to impose high BER at Eve, without providing any promise of information theoretic security. Moreover, some shaping schemes, e.g. GS and PAS, need to work with a BICM structure and/or a DM, which makes the analysis of information leakage challenging. Due to the above considerations, we turn to multilevel polar coding since polar codes have shown the ability to achieve the secrecy capacity of binary-input symmetric DMWC [8] and the capacity of constellation-input asymmetric DMC [27].

In this paper, we propose a probabilistic shaped multilevel polar coding scheme achieving the secrecy capacity of the Gaussian wiretap channel with discrete constellation input. We investigate the polarization for the asymmetric DMWC with constellation input, leading to a random bit set and a shaping bit set in addition to the information bit set and frozen bit set in conventional polar codes. These two additional sets are considered separately in [8] and [27], respectively. Hence, we need to take into account the simultaneous introduction of the two sets and re-establish the conclusions on capacity achieving, reliability, and security, following the basic ideas in [8] and [27]. Furthermore, since the secrecy capacity achieving input distribution is the one that maximizes the secrecy rate rather than the mutual information as in conventional shaping schemes, an input distribution optimization problem for the Gaussian wiretap channel should be solved. To enable secure transmission, a practical code construction method under security condition constraint should also be investigated. The main contributions of this paper are detailed as follows.

- We formulate the problem of optimizing the input distribution to maximize the secrecy rate of the Gaussian wiretap channel under discrete constellation input constraints, and simplify the problem by adopting the Maxwell-Boltzmann (MB) distribution. Specifically, given an ASK/QAM constellation input, a sub-optimal solution can be found by traversing the feasible interval. Numerical results show that the sub-optimal solution achieves a secrecy rate close to the Gaussian secrecy capacity with negligible gap.
- 2) We propose a probabilistic shaped multilevel polar coding scheme. For the asymmetric DMWC with discrete constellation input, we show that the bit positions of a multilevel polar code will asymptotically polarize into four sets, which are placed with frozen bits, message bits, random bits and shaping bits, respectively. Such a polar code is proven to be secrecy capacity achieving and to satisfy the reliability condition and the weak security condition as code length goes to infinity. We also remark that the above conclusions apply to the degraded Gaussian wiretap channel.
- 3) We propose a security-oriented polar code construction method for the proposed coding scheme at finite block length regimes, which natively satisfies the leakagebased security condition given a desired security gap. For completeness, the encoding and decoding procedures and complexity analysis are also provided.
- 4) Simulation results show that the proposed scheme can achieve more efficient and secure transmission than the uniform input case over both the Gaussian wiretap channel and the Rayleigh fading (RF) wiretap channel, and the results corroborate the theoretical conclusions.

The rest of the paper is organized as follows. Section II introduces some essential preliminaries. In Section III, we solve the input distribution optimization problem for maximizing the secrecy rate. The probabilistic shaped multilevel polar coding scheme is proposed in Section IV. Section V introduces the coding procedure and code construction method. Section VI presents our simulation results. Finally, Section VII concludes this paper.

Notations: Random variables are denoted by uppercase letters, e.g., X, while their realizations are denoted by lowercase letters, e.g., x. We denote P_X and E[X] by the probability distribution and expectation of X, respectively. Vectors are denoted by bold symbols, e.g., X. The notations H(X), H(X|Y) and I(X;Y) indicate the entropy of X, the entropy of X conditioned on Y and the mutual information (MI) of X and Y, respectively. The probability of an event is written as $Pr\{\cdot\}$. Sets like alphabet are denoted by calligraphic letters, e.g., \mathcal{X} . \mathcal{X}^C and $|\mathcal{X}|$ are the complement and cardinality of \mathcal{X} , respectively. The set difference is defined as $\mathcal{X} \setminus \mathcal{Y} = \mathcal{X} \cap \mathcal{Y}^C$.

¹For asymmetric settings, the capacity achieving input distribution of the codewords is not always uniform.

Fig. 1. The wiretap channel model.

We denote the real field, positive integer set and binary field by \mathbb{R} , \mathbb{N} and \mathbb{F}_2 , respectively. The empty set is denoted by \emptyset . An index set $\{1, 2, \dots, N\}$ is abbreviated as $[\![N]\!]$, and particularly $[\![0]\!]$ is equal to \emptyset . Given a vector \boldsymbol{x} of length N and $\mathcal{A} \subseteq [\![N]\!]$, we write $\boldsymbol{x}_{\mathcal{A}}$ to denote the sub-vector $[x_i]_{i \in \mathcal{A}}$.

II. PRELIMINARIES

A. Wiretap Channel Model

The well-known wiretap channel model [2] is shown in Fig. 1. A transmitter Alice wants to send a K-bit uniformly distributed message M to the legitimate receiver Bob, while the transmission is wiretapped by an eavesdropper Eve. The message M is encoded and mapped to a symbol sequence X of length N. Each element of X is taken from the constellation \mathcal{X} of cardinality $Q = |\mathcal{X}|$. Bob and Eve receive X through their respective channels. The channel observations of Bob and Eve are denoted by Y and Z, respectively. We assume that the coding scheme is perfectly known by both Bob and Eve. Thus, the observations Y and Z can be demapped and decoded to estimate \hat{M}_B and \hat{M}_E , respectively.

B. Secrecy Metrics

1) Reliability and Security: In the wiretap channel model, Alice's transmission should achieve two objectives—reliability and security. Reliability means that Bob can reconstruct Mwith negligibly probability of error. Specifically, the reliability condition is given by

$$\lim_{K \to \infty} \Pr\{\hat{\boldsymbol{M}}_B \neq \boldsymbol{M}\} = 0.$$
 (1)

Security refers to preventing Eve from extracting any information about M. Usually, security is measured in terms of the number of bits leaked to Eve, also denoted as the *information leakage* I(M; Z). Specifically, the *weak security* condition is defined as the leakage per coded symbol vanishes for infinite symbol length, i.e.,

$$\lim_{N \to \infty} \frac{1}{N} I(\boldsymbol{M}; \boldsymbol{Z}) = 0$$
(2)

while the *strong security* condition [28] is defined as the leakage itself vanishes for infinite symbol length, i.e.,

$$\lim_{N \to \infty} I(\boldsymbol{M}; \boldsymbol{Z}) = 0.$$
(3)

2) Secrecy Capacity: The secrecy capacity defines the maximum theoretical transmission rate for reliable communication between Alice and Bob, while keeping Eve ignorant of the message. Specifically, for a degraded DMWC, i.e., Eve's channel is a degraded version of Bob's channel, the achievable secrecy rate R_s is calculated by

$$R_s = I(X;Y) - I(X;Z) \tag{4}$$

which is an upper bound on the transmission rate achieving both reliable and secure communication with a given input distribution P_X of X. Then, the secrecy capacity is the maximum R_s taken over all possible input distributions P_X [2], [29], i.e.,

$$C_s = \max_{P_X} R_s = \max_{P_X} \left[I(X;Y) - I(X;Z) \right].$$
 (5)

3) Equivocation Rate: As a measure of Eve's uncertainty about the message M from his observation Z, the equivocation rate is calculated by

$$R_e = \frac{1}{N} H(\boldsymbol{M} | \boldsymbol{Z}).$$
 (6)

Let the transmission rate be $R_t = K/N$. A rate-equivocation pair $(\tilde{R}_t, \tilde{R}_e)$ is said to be achievable if, for all $\epsilon > 0$, there exists a code sequence of rate R_t such that

$$\begin{cases} \lim_{N \to \infty} R_t \ge \tilde{R}_t - \epsilon, \\ \lim_{N \to \infty} R_e \ge \tilde{R}_e - \epsilon, \\ \lim_{N \to \infty} \Pr\{\hat{M}_B \ne M\} \le \epsilon. \end{cases}$$
(7)

The rate-equivocation region is defined as the closure of all achievable rate-equivocation pairs $(\tilde{R}_t, \tilde{R}_e)$. Consider a degraded wiretap channel with a fixed input distribution $P_X(x)$, the achievable rate-equivocation region is given by [2]

$$\begin{cases} \dot{R}_e \le \dot{R}_t \le I(X;Y), \\ 0 \le \tilde{R}_e \le R_s. \end{cases}$$
(8)

4) Security Gap: The secrecy metrics introduced above are information theoretic, which are difficult to compute in many practical coding scenarios and finite block length regimes. To this point, Klinc et al. proposed a practical secrecy metric named security gap that is measured by BER [9]. Specifically, let P_e^B and P_e^E denote the average BER of Bob and Eve, respectively. Given a reliability threshold $P_{e,\max}^B$ and a security threshold $P_{e,\max}^E$, while the security condition is said to be satisfied if $P_e^B \leq P_{e,\max}^B$, while the security condition is said to be achieved if $P_e^E \geq P_{e,\min}^E$. Assuming that Bob's and Eve's channels are corrupted by AWGN, the security gap is given by

$$S_g = \frac{\text{SNR}_{B,\min}}{\text{SNR}_{E,\max}} \tag{9}$$

where $\text{SNR}_{B,\min}$ denotes the minimum required signal-tonoise ratio (SNR) of Bob's channel to achieve the reliability condition and $\text{SNR}_{E,\max}$ denotes the maximum SNR of Eve's channel to ensure the security condition. This metric defines how much the degradation of Eve's channel with respect to Bob's channel needs to be to achieve a secure transmission. Obviously, the security gap is expected to be as small as possible.

Moreover, when applying polar codes, the security can also

be measured by the estimated information leakage. Benefiting from the special structure of polar codes, the amount of information leaked to Eve can be estimated by a modified successive cancellation (SC) decoder [30] or some polar construction methods [31], [32]. Similar to the security condition in the form of BER, the leakage-based security condition is defined as $L_k^E \leq L_{k,\max}^E$, where L_k^E denotes the estimation of the normalized information leakage $I(\boldsymbol{M}; \boldsymbol{Z})/K$ and $L_{k,\max}^E$ denotes the security threshold. In this case, the definition of the security gap still holds.

C. Polar Codes

Polar codes, proposed by Arıkan, are known as the first channel coding scheme proven to achieve the symmetric capacity of arbitrary binary-input DMC (B-DMC) [33]. Let $W: X \to Y$ be a B-DMC with input alphabet $\mathcal{X} = \{0, 1\}$ and output alphabet \mathcal{Y} . Considering polar codes with block length $N = 2^n$ for $n \in \mathbb{N}$, the polar transform maps an input vector $\boldsymbol{u} \in \mathbb{F}_2^N$ to a codeword $\boldsymbol{x} \in \mathbb{F}_2^N$ by using

$$\boldsymbol{x} = \boldsymbol{u}\boldsymbol{G}_N$$
 with $\boldsymbol{G}_N = \boldsymbol{B}_N\boldsymbol{G}^{\otimes n}$ (10)

where B_N is the bit-reversal matrix as in [33] and $G^{\otimes n}$ denotes the *n*-th Kronecker power of $G = \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}$. The generator matrix G_N satisfies $G_N^{-1} = G_N$. Then, the codeword x is transmitted over N independent uses of the B-DMC W and the received signal vector is $y \in \mathcal{Y}^N$. With SC decoding, the transition probability of the *i*-th sub-channel is given by

$$W_N^{(i)}\left(\boldsymbol{u}_{[[i-1]]}, \boldsymbol{y}|u_i\right) = P_{\boldsymbol{U}_{[[i-1]]}, \boldsymbol{Y}|U_i}\left(\boldsymbol{u}_{[[i-1]]}, \boldsymbol{y}|u_i\right).$$
(11)

Arıkan showed that the bits in u asymptotically polarize into two sets [33]:

$$\mathcal{G} = \left\{ i \in \llbracket N \rrbracket : Z_B \left(U_i | \boldsymbol{U}_{\llbracket i-1 \rrbracket}, \boldsymbol{Y} \right) < \delta_N \right\},$$
(12)

$$\mathcal{B} = \left\{ i \in \llbracket N \rrbracket : Z_B \left(U_i | \boldsymbol{U}_{\llbracket i-1 \rrbracket}, \boldsymbol{Y} \right) > 1 - \delta_N \right\}$$
(13)

where $\delta_N \triangleq 2^{-N^{\beta}}$ for any $\beta \in (0, \frac{1}{2})$ and $Z_B(\cdot|\cdot)$ denotes the Bhattacharyya parameter. More specifically, given that $(T, V) \sim P_{T,V}$ is an arbitrary pair of random variables, where $T \in \mathbb{F}_2$ and V takes values in an arbitrary alphabet \mathcal{V} , the Bhattacharyya parameter [34] is defined as

$$Z_B(T|V) = 2\sum_{v \in \mathcal{V}} P_V(v) \sqrt{P_{T|V}(0|v)P_{T|V}(1|v)}$$

= $2\sum_{v \in \mathcal{V}} \sqrt{P_{T,V}(0,v)P_{T,V}(1,v)}$ (14)

and satisfies that $Z_B(T|V)$ is close to 0 or 1 if and only if H(T|V) is close to 0 or 1 [34, Proposition 2], respectively. Therefore, the general idea of polar codes is to use the positions indexed by \mathcal{G} for data transmission, while the remaining positions in \boldsymbol{u} are filled with *frozen* bits, which are set to fixed values known to both transmitter and receiver. As such, the data bit U_i , $i \in \mathcal{G}$, can be successively determined by $\boldsymbol{U}_{[[i-1]]}$ and \boldsymbol{Y} since $H(U_i|\boldsymbol{U}_{[[i-1]]}, \boldsymbol{Y}) \approx 0$.

III. OPTIMIZATION OF THE INPUT DISTRIBUTION FOR THE GAUSSIAN WIRETAP CHANNEL

We consider the Gaussian wiretap channel with ASK input, where the channel input X is taken from a Q-ary ASK constellation $\mathcal{X} = \{\pm 1, \pm 3, \dots, \pm (Q-1)\}$ with distribution P_X . Assuming that the transmit power is P, we scale X by the constellation scaling factor $\Delta > 0$ to satisfy the power constraint. Thereby, the received signals at the legitimate receiver and the eavesdropper are given by

$$Y = \Delta X + N_B,\tag{15}$$

$$Z = \Delta X + N_E \tag{16}$$

respectively, where N_B and N_E follow the independent and identically distributed (i.i.d.) complex Gaussian distribution with zero-mean and variances σ_B^2 and σ_E^2 , i.e., $N_B \sim C\mathcal{N}(0, \sigma_B^2)$ and $N_E \sim C\mathcal{N}(0, \sigma_E^2)$. We denote the SNRs of Bob's channel and Eve's channel by $\text{SNR}_B = P/\sigma_B^2$ and $\text{SNR}_E = P/\sigma_E^2$, respectively. If Eve's channel is degraded with respect to Bob's channel, we have $\text{SNR}_B > \text{SNR}_E$.

To narrow the gap between the achievable secrecy rate with uniformly distributed ASK input and the Gaussian secrecy capacity, we formulate the following input distribution optimization problem

$$\max_{P_{\mathbf{x}}} R_s \quad \text{s.t. } E\left[|\Delta X|^2\right] = P \tag{17}$$

where R_s is specifically calculated by (18) at the top of next page. Since the secrecy capacity of the Gaussian wiretap channel is achieved by Gaussian input [3], we use the MB distribution family

$$P_{X_{\nu}}(x) = \frac{e^{-\nu x^2}}{\sum_{x' \in \mathcal{X}} e^{-\nu x'^2}}, \ x \in \mathcal{X}$$
(19)

with the parameter $\nu \geq 0$, which is a discrete Gaussian-like distribution that maximizes the entropy of the channel inputs subject to the power constraint [35]. Thus, for a given scaling factor Δ , we choose the input distribution

$$P_{X_{\Delta}}(x) = P_{X_{\nu}}(x) \quad \text{with} \quad \nu : E\left[|\Delta X_{\nu}|^2\right] = P.$$
 (20)

As $E[|X_{\nu}|^2]$ is strictly monotonically decreasing in ν [23], the value of ν can be found efficiently by the *bisection method*. Moreover, for $\nu = 0$, the value of $E[|X_{\nu}|^2]$ equals to $(Q^3 - Q)/6$ and converges to 1 for $\nu \to \infty$. As such, (17) simplifies to an optimization problem over Δ as follows

$$\max_{\Lambda} R_s \tag{21a}$$

s.t.
$$\sqrt{\frac{6P}{Q^3-Q}} \le \Delta < \sqrt{P},$$
 (21b)

$$P_X(x) = P_{X_\Delta}(x). \tag{21c}$$

We note that the optimization problem (21) differs from the optimization problem that maximizes mutual information I(X;Y) in [23] because I(X;Y) is an unimodal function of Δ , while R_s is not (in fact, we find that R_s is a bimodal function of Δ by numerical results). Hence, we propose to solve the optimization problem by traversing the feasible

$$R_{s} = \sum_{x_{i} \in \mathcal{X}} P_{X}(x_{i}) \left(E_{N_{E}} \left[\log_{2} \sum_{x_{j} \in \mathcal{X}} \frac{P_{X}(x_{j})}{P_{X}(x_{i})} \exp\left(-\frac{|n_{E} + \Delta(x_{i} - x_{j})|^{2} - |n_{E}|^{2}}{\sigma_{E}^{2}}\right) \right] - E_{N_{B}} \left[\log_{2} \sum_{x_{j} \in \mathcal{X}} \frac{P_{X}(x_{j})}{P_{X}(x_{i})} \exp\left(-\frac{|n_{B} + \Delta(x_{i} - x_{j})|^{2} - |n_{B}|^{2}}{\sigma_{B}^{2}}\right) \right] \right).$$
(18)

Fig. 2. The achievable secrecy rate for the Gaussian wiretap channel with Gaussian input, shaped Q-ASK input and uniform Q-ASK input, where $Q \in \{2, 4, 8, 16, 32, 64\}$ and $SNR_B - SNR_E = 3$ dB.

interval (21b) with a small step size and thus shape the input distribution to an MB distribution that maximizes the achievable secrecy rate R_s . The resulting scaling factor and the corresponding input distribution are denoted by Δ^* and P_{X^*} , respectively. Note that the distribution P_{X^*} is a suboptimal solution to (17) in general, due to the choice of MB distribution family and the way we traverse the interval (21b). However, the following simulations will show that the gain from further optimizing is negligible.

Fig. 2 depicts the achievable secrecy rate versus SNR_B for shaped ASK constellation input with distribution P_{X^*} , where P_{X^*} is found with a step size equal to 10^{-4} , and SNR_E is set always to be 3 dB lower than SNR_B . For comparison, the performances of Gaussian input and uniformly distributed ASK input are also provided. It is observed in Fig. 2 that the shaped ASK input achieves a secrecy rate higher than the uniform case and close to the Gaussian capacity. For a certain cardinality Q, limited by finite constellation input, the shaped input has the same drawback as the uniform input, that is, the secrecy rate will drop to zero when SNR_B is high enough. Nevertheless, as the cardinality Q of the ASK constellation increases, the shaped ASK input almost eliminates the gap between the Gaussian capacity and the secrecy rate achieved by the uniform ASK input, which confirms that our solution to the optimization problem (17) is effective enough.

Note that since the QAM signal can be generated by

a pair of orthogonal ASK signals, the method for solving optimization problem (17) in this section is also applicable to QAM constellations. In addition, we highlight that some P_{X*} can be computed with a certain step size for SNRs beforehand and stored. Then, given an SNR_B and an SNR_E, we may acquire an optimized distribution via linear fitting in practical use.

IV. PROBABILISTIC SHAPED MULTILEVEL POLAR CODING SCHEME

After optimizing the input distribution, we need a practical coding scheme to achieve the desired input distribution while ensuring secure transmission. In this section, we propose a multilevel polar coding scheme to achieve the secrecy capacity of the asymmetric DMWC with constellation input, and also show that the scheme works for the Gaussian wiretap channel.

A. Polarization of Multilevel Polar Codes for the Asymmetric DMWC

Let $W_1: X \to Y$ and $W_2: X \to Z$ be Bob's channel and Eve's channel, respectively. We assume that W_2 is degraded with respect to W_1 , denoted as $W_2 \preceq W_1$. The input alphabet \mathcal{X} is of cardinality $Q = |\mathcal{X}| = 2^q$. We consider the multilevel polar coding construction [36] shown in Fig. 3. A codeword \boldsymbol{x} consists of $N = 2^n$ symbols, while each symbol $x_i, i \in$ [N], is labelled with q bits. We denote the symbol mapping function by $f(\cdot)$, i.e., $x_i = f(\boldsymbol{b}_i) = f(b_i^1, b_i^2, \cdots, b_i^q)$, where $f(\cdot)$ is invertible. Here, we use the set-partitioning labeling since it outperforms the classic Gary labeling in MLC [36]. For each bit-level, b^l , $l \in [[q]]$, is generated by a separate polar transform $b^l = u^l G_N$ of length N. At the receiver, the multistage decoding (MSD) [37] outputs the estimates \hat{u}^l of u^l level-by-level, as shown in Fig. 4. Specifically, the demapper at *l*-th bit-level calculates the log-likelihood ratios (LLRs) \boldsymbol{L}_R^l given the channel observation y and previous estimates $\hat{b}^{[l-1]}$, and then feeds L_{R}^{l} to a polar decoder to obtain the estimates $\hat{\boldsymbol{b}}^l$ and $\hat{\boldsymbol{u}}^l$.

With the MLC and MSD construction, b^l is transmitted over equivalent binary-input sub-channels $W_1^l : B^l \to (Y, \mathbf{B}^{[l-1]})$ and $W_2^l : B^l \to (Z, \mathbf{B}^{[l-1]})$. The degradation of the subchannel W^l is described as follows.

Lemma 1: Let $W_1 : X \to Y$ and $W_2 : X \to Z$ be two DMCs with input alphabet \mathcal{X} of cardinality $|\mathcal{X}| = 2^q$. The input symbol X is mapped by $f(\mathbf{B}) = f(B^1, B^2, \dots, B^q)$. Consider the equivalent binary-input sub-channels $W_1^l : B^l \to$

Fig. 3. The multilevel polar coding construction with Q = 8 and N = 4.

 $(Y, B^{[l-1]})$ and $W_2^l : B^l \to (Z, B^{[l-1]})$ for the *l*-th bit-level, $l \in \llbracket q \rrbracket$. If $W_2 \preceq W_1$, then $W_2^l \preceq W_1^l$.

Proof: See Appendix A.

Hence, b^l is transmitted over a degraded binary-input DMWC. By using polar transform $b^l = u^l G_N$, the degrada-tion of the *i*-th bit-channel $W_N^{l(i)}$ at the *l*-th bit-level is given by the following lemma.

Lemma 2 (Degradation of $\bar{W}_N^{(i)}$ [38, Lemma 4.7]): Let \bar{W}_1 : $X \to Y$ and $\overline{W}_2 : X \to Z$ be two B-DMCs such that $\overline{W}_2 \preceq \overline{W}_1$, then for all $i \in [\![N]\!], \ \overline{W}_{2,N}^{(i)} \preceq \overline{W}_{1,N}^{(i)}$.

From Lemma 2, we immediately have that $W_{2,N}^{l(i)} \preceq W_{1,N}^{l(i)}$ for $l \in [\![q]\!]$ and $i \in [\![N]\!]$. Then, in the following lemma, we show that the degradation of the bit-channel $W_N^{l(i)}$ will increase the Bhattacharyya parameter.

Lemma 3: Let $\bar{W}_1: X \to Y$ and $\bar{W}_2: X \to Z$ be two B-DMCs. Consider a polar transform $X = UG_N$. Let $\overline{W}_{1,N}^{(i)}$: $U_i
ightarrow oldsymbol{Y}$ and $ar{W}_{2,N}^{(i)}: U_i
ightarrow oldsymbol{Z}$ be two bit-channels with side information \boldsymbol{S} for $i \in [\![N]\!]$. If $\bar{W}_{2,N}^{(i)} \preceq \bar{W}_{1,N}^{(i)}$, we then have

$$Z_B(U_i|\boldsymbol{S},\boldsymbol{Y}) \leq Z_B(U_i|\boldsymbol{S},\boldsymbol{Z})$$

Proof: See Appendix B.

Now, we consider the sets

$$\mathcal{L}_X = \left\{ (l,i) : Z_B \left(U_i^l | \mathbf{V}_i^l \right) < \delta_N \right\},\tag{22}$$

$$\mathcal{H}_X = \left\{ (l,i) : Z_B \left(U_i^l | \mathbf{V}_i^l \right) > 1 - \delta_N \right\}, \qquad (23)$$

$$\mathcal{L}_{X|Y} = \left\{ (l,i) : Z_B \left(U_i^l | \mathbf{V}_i^l, \mathbf{Y} \right) < \delta_N \right\}, \tag{24}$$

$$\mathcal{H}_{X|Y} = \left\{ (l,i) : Z_B \left(U_i^l | \boldsymbol{V}_i^l, \boldsymbol{Y} \right) > 1 - \delta_N \right\}$$
(25)

where $l \in [\![q]\!]$, $i \in [\![N]\!]$, and $V_i^l = (U_{[\![i-1]\!]}^l, B_{[\![N]\!]}^{[\![l-1]\!]})$. Recall the fact that $Z_B(\cdot|\cdot)$ and $H(\cdot|\cdot)$ are close to 0 or 1 simultaneously. Therefore, U_i^l is approximately a deterministic function of V_i^l and Y for $(l,i) \in \mathcal{L}_{X|Y}$, while U_i^l is approximately uniformly distributed and independent of V_i^l and Y for $(l,i) \in \mathcal{H}_{X|Y}$. In other words, the bit positions indexed by $\mathcal{L}_{X|Y}$ are suitable for data transmission, since we can successively recover U_i^l given the channel output Y and the sequence V_i^l with MSD and SC decoding. Meanwhile, for $(l,i) \in \mathcal{H}_X, U_i^l$ is almost independent of V_i^l , while U_i^l is almost a deterministic function of V_i^l for $(l, i) \in \mathcal{L}_X$. Hence, if $(l,i) \in \mathcal{L}_X$, U_i^l can not be used for data transmission, but

Fig. 4. The MSD construction with Q = 8.

needs to be successively chosen in a specific way based on the previous input V_i^l . The polarization of these sets is given as follows.

Proposition 1: Let $W : X \to Y$ be a DMC with input alphabet \mathcal{X} of cardinality $|\mathcal{X}| = 2^q$. Let $B^l, l \in [\![q]\!]$, be the *l*-th bit of the binary representation \boldsymbol{B} of symbol $X = f(\boldsymbol{B})$, and let $B^l = U^l G_N$. The sets \mathcal{L}_X , \mathcal{H}_X , $\mathcal{L}_{X|Y}$ and $\mathcal{H}_{X|Y}$ are defined by (22)-(25), respectively. As $N \to \infty$, we asymptotically have

$$q - \lim_{N \to \infty} \frac{1}{N} \left| \mathcal{L}_X \right| = \lim_{N \to \infty} \frac{1}{N} \left| \mathcal{H}_X \right| = H(X), \quad (26)$$

$$q - \lim_{N \to \infty} \frac{1}{N} \left| \mathcal{L}_{X|Y} \right| = \lim_{N \to \infty} \frac{1}{N} \left| \mathcal{H}_{X|Y} \right| = H(X|Y).$$
(27)
Proof: See Appendix C.

Proof: See Appendix C.

Let $\mathcal{L}_{X|Z}$ and $\mathcal{H}_{X|Z}$ be the two sets defined in the similar way as $\mathcal{L}_{X|Y}$ and $\mathcal{H}_{X|Y}$, respectively. By Lemma 3 and the fact that conditioning reduces the Bhattacharyya parameter [39, Lem. 6], we have

$$\mathcal{L}_X \subseteq \mathcal{L}_{X|Z} \subseteq \mathcal{L}_{X|Y}.$$
(28)

This reveals that although the bits at positions indexed by $\mathcal{L}_{X|Y}$ can be successively recovered by Bob, the bits at positions indexed by $\mathcal{L}_{X|Z}$ among them will be directly leaked to Eve. To achieve secure transmission, not all bit positions indexed by $\mathcal{L}_{X|Y}$ are suitable for message transmission, where the bit positions indexed by $\mathcal{L}_{X|Z}$ can only be filled with some useless information to Eve.

Thus, we divide the index set $\{(l,i) : l \in [\![q]\!], i \in [\![N]\!]\}$ of a multilevel polar code into four sets:

$$\mathcal{F} = \mathcal{L}_{X|Y}^C,\tag{29}$$

$$\mathcal{A} = (\mathcal{L}_{X|Y} \cap \mathcal{H}_X) \setminus (\mathcal{L}_{X|Z} \cap \mathcal{H}_X), \tag{30}$$

$$\mathcal{R} = \mathcal{L}_{X|Z} \cap \mathcal{H}_X,\tag{31}$$

$$\mathcal{D} = \mathcal{L}_{X|Y} \cap \mathcal{H}_X^C. \tag{32}$$

It is immediately obtained that the sets $\mathcal{F}, \mathcal{A}, \mathcal{R}, \mathcal{D}$ are disjoint and $\mathcal{F} \cup \mathcal{A} \cup \mathcal{R} \cup \mathcal{D} = \{(l, i) : l \in [\![q]\!], i \in [\![N]\!]\}$ by (28). The polarization of such a polar code is described as follows.

Theorem 1: Let W_1 : $X \to Y$ and W_2 : $X \to Z$ be two DMCs such that $W_2 \preceq W_1$. The input alphabet $\mathcal X$ is of cardinality $|\mathcal{X}| = 2^q$. Let B^l , $l \in [\![q]\!]$, be the *l*-th bit of the binary representation \boldsymbol{B} of symbol $X = f(\boldsymbol{B})$, and let $B^{l} = U^{l}G_{N}$. Given the sets $\mathcal{F}, \mathcal{A}, \mathcal{R}$ and \mathcal{D} defined by (29)-(32), respectively, we asymptotically have

Fig. 5. Graphical representation of the polarization of $Z_B(U_i|V_i^l, Z)$, $Z_B(U_i|V_i^l, Y)$ and $Z_B(U_i|V_i^l)$ as $N \to \infty$.

$$\lim_{N \to \infty} \frac{1}{N} |\mathcal{F}| = H(X|Y), \tag{33}$$

$$\lim_{N \to \infty} \frac{1}{N} |\mathcal{A}| = I(X;Y) - I(X;Z), \tag{34}$$

$$\lim_{N \to \infty} \frac{1}{N} |\mathcal{R}| = I(X; Z), \tag{35}$$

$$\lim_{N \to \infty} \frac{1}{N} |\mathcal{D}| = q - H(X).$$
(36)

Proof: See Appendix D.

A graphical representation of the polarization is illustrated in Fig. 5. If the bit positions \mathcal{A} are placed with uniformly distributed message, Theorem 1 and (4) tell us that the multilevel polar codes above can asymptotically achieve the secrecy rate R_s when the input distribution P_X is given. Note that if P_X is an optimal solution to (17), such polar codes can be proved to achieve the secrecy capacity of asymmetric DMWC with constellation input by Theorem 1 and (5). However, our optimized sub-optimal input distribution P_{X^*} will remain a negligible gap between the achievable secrecy rate and the security capacity as verified in Sec. III.

B. Proposed Coding Scheme

Based on the polarization phenomenon above, the general idea of our coding scheme for asymmetric DMWC with constellation input is summarized as follows.

- The positions indexed by A are used for transmitting uniformly distributed message M.
- The positions indexed by \mathcal{R} are placed with uniform *random bits*. The random bits here are to keep Eve ignorant since Eve has the ability to successfully recover these random bits.
- The positions indexed by \mathcal{D} are placed with *shaping bits*, which are chosen successively according to the *randomized rounding rule* [24] or the *argmax rule* [40]. We will describe this in more detail in Section V-A.
- The remaining positions, i.e., indexed by \mathcal{F} , are filled with *frozen bits*, which are set to fixed values that are known both at the transmitter and the receiver.

C. Reliability Analysis

Recall that M and M_B denote Alice's message and Bob's observation, respectively. Our coding scheme satisfies the reliability condition (1) by the following theorem.

Theorem 2: Let $W_1 : X \to Y$ and $W_2 : X \to Z$ be two DMCs with constellation input such that $W_2 \preceq W_1$. Consider the coding scheme proposed above. For any $0 < \beta' < \beta < 1/2$, the average block error probability is upper bounded by

$$\Pr\{\hat{M}_B \neq M\} \le c2^{-N^{\beta}} \tag{37}$$

where c is a positive constant. As $K \to \infty$, we have

$$\lim_{K \to \infty} \Pr\{\hat{\boldsymbol{M}}_B \neq \boldsymbol{M}\} = 0.$$
(38)

Proof: Since $\mathcal{A} \subseteq (\mathcal{L}_{X|Y} \cap \mathcal{H}_X)$, there is a positive constant c so that (37) holds with $0 < \beta' < \beta < 1/2$ by [27, Theorem 2]. Then, since $K = \Theta(N)$, it is easy to prove that (38) holds.

D. Security Analysis

Observing that $U_{\mathcal{A}} = M$, $U_{\mathcal{F}} = 0$ (for simplicity), $U_{\mathcal{R}}$ is uniform over $\{0,1\}^{|\mathcal{R}|}$, and $U_{\mathcal{D}}$ is determined by $U_{\mathcal{D}^{\mathcal{C}}}$. Let $h_2(\cdot)$ be the binary entropy function. We first present the following lemma that is helpful to the proof of security.

Lemma 4:

$$H(\boldsymbol{U}_{\mathcal{R}}|\boldsymbol{Z},\boldsymbol{U}_{\mathcal{A}}) \le h_2(c2^{-N^{\beta'}}) + c|\mathcal{R}|2^{-N^{\beta'}}.$$
 (39)

Proof: See Appendix E.

Now, we show that our coding scheme satisfies the weak security condition (2) in the following theorem.

Theorem 3: Let $W_1 : X \to Y$ and $W_2 : X \to Z$ be two DMCs with constellation input such that $W_2 \preceq W_1$. The information leakage per symbol of the proposed coding scheme vanishes as $N \to \infty$, namely

$$\lim_{N \to \infty} \frac{I(\boldsymbol{M}; \boldsymbol{Z})}{N} = 0.$$
(40)

Proof: See Appendix F.

Remark 1: Along the lines of [41, Part IV, Appendix 7], Theorems 1, 2 and 3 can be easily extended to discrete-input, continuous-output degraded wiretap channels, such as the degraded Gaussian wiretap channel with constellation input.

V. CODING FOR FINITE BLOCK LENGTH

At finite block length regimes, the coding procedure and a general code construction method are introduced as follows.

A. Encoding and Decoding

At the encoder, the bit positions \mathcal{A} , \mathcal{R} and \mathcal{F} in u are directly placed with information bits, uniform random bits and frozen bits, respectively, while u_i^l , $(l, i) \in \mathcal{D}$, is chosen by performing an MSD with SC decoding. More specifically, for each bit-level l, the MSD computes $P_{B^l|B^{l-1}}(\cdot|\mathbf{b}_i^{\mathbb{I}^{l-1}})$ given

a desired input distribution P_X , $i \in [N]$ [37]. Then, the SC decoder is initialized with a priori LLR

$$L_{R} = \log \frac{P_{B^{l}|\boldsymbol{B}^{[l-1]}}(0|\boldsymbol{b}_{i}^{[l-1]})}{P_{B^{l}|\boldsymbol{B}^{[l-1]}}(1|\boldsymbol{b}_{i}^{[l-1]})}$$
(41)

for all $i \in [\![N]\!]$, and successively outputs the probability $P_{U_i^l|V_i^l}(\cdot|v_i^l)$. Honda and Yamamoto proposed to determine u_i^l , $(l,i) \in \mathcal{D}$, by the following randomized rounding rule [24]:

$$u_{i}^{l} = \begin{cases} 0 & \text{with probability } P_{U_{i}^{l}|\boldsymbol{V}_{i}^{l}}\left(0|\boldsymbol{v}_{i}^{l}\right), \\ 1 & \text{with probability } P_{U_{i}^{l}|\boldsymbol{V}_{i}^{l}}\left(1|\boldsymbol{v}_{i}^{l}\right) \end{cases}$$
(42)

where the random number generator is shared between the transmitter and the receiver. To avoid randomness, the authors in [40] introduced an alternative rule called argmax rule, which is given by

$$u_{i}^{l} = \begin{cases} 0, & P_{U_{i}^{l}|\boldsymbol{V}_{i}^{l}}\left(0|\boldsymbol{v}_{i}^{l}\right) \geq P_{U_{i}^{l}|\boldsymbol{V}_{i}^{l}}\left(1|\boldsymbol{v}_{i}^{l}\right), \\ 1, & P_{U_{i}^{l}|\boldsymbol{V}_{i}^{l}}\left(0|\boldsymbol{v}_{i}^{l}\right) < P_{U_{i}^{l}|\boldsymbol{V}_{i}^{l}}\left(1|\boldsymbol{v}_{i}^{l}\right). \end{cases}$$
(43)

After all the values in u are determined, the codeword x is generated by the polar transform $b^l = u^l G_N$ and the symbol mapping function f(b).

However, the hard decision of u_i^l may not achieve the desired distribution of X at finite block length regimes. To alleviate this issue, we perform a list encoding by replacing the SC decoder with a successive cancellation list (SCL) decoder. As such, we obtain a list of valid codewords and choose the one that has an empirical distribution closest to the desired distribution as the output of the list encoder.

As Bob and Eve perform the same decoding procedure, we take Bob's decoder as an example. The decoder computes the estimate \hat{u} of u from the channel observations y by using the MSD structure with SC decoding or SCL decoding. For $(l,i) \in \mathcal{F}, \hat{u}_i^l$ is set to the frozen value. Otherwise, \hat{u}_i^l is estimated according to

$$\hat{u}_{i}^{l} = \arg \max_{u \in \{0,1\}} P_{U_{i}^{l} | \boldsymbol{V}_{i}^{l}, \boldsymbol{Y}} \left(u | \boldsymbol{v}_{i}^{l}, \boldsymbol{y} \right).$$
(44)

Note that since the random bits with index set \mathcal{R} are unknown to the receiver, we treat them as message bits when decoding. Moreover, \hat{u}_i^l with $(l,i) \in \mathcal{D}$ should actually be estimated by $\arg \max_{u \in \{0,1\}} P_{U_i^l | V_i^l, Y}(u | v_i^l)$. Yet, by the fact that $H(U_i^l | V_i^l, Y) \leq H(U_i^l | V_i^l)$, it holds that $H(U_i^l | V_i^l, Y)$ is close to zero if $H(U_i^l | V_i^l)$ is close to zero. Hence, we can still estimate \hat{u}_i^l reliably by (44) instead of running an additional decoder. Furthermore, when applying SCL decoding in MSD, the list and path metric of the SCL decoder at each bit-level should to be passed to the next level. To address this, the MSD with SCL decoding performs the same steps as the list multistage decoder in [26].

B. Code Construction

For convenience, we first denote $|\mathcal{F}|$, $|\mathcal{A}|$, $|\mathcal{R}|$ and $|\mathcal{D}|$ by F, K, R, and D, respectively. The code construction includes the determination of the values of F, K, R, and D and the selection of the sets $\mathcal{F}, \mathcal{A}, \mathcal{R}$, and \mathcal{D} .

Let $d\text{SNR}_B$ and $d\text{SNR}_g$ be the desired SNRs that Bob's BER P_e^B at $d\text{SNR}_B$ satisfies the reliability condition $P_e^B \leq P_{e,\max}^B$ and information leakage L_k^E at $d\text{SNR}_B - d\text{SNR}_g$ satisfies the security condition $L_k^E \leq L_{k,\max}^E$, where $P_{e,\max}^B$ and $L_{k,\max}^E$ are the thresholds introduced in Sec. II-B. Observing that P_e^B is an increasing function of K + R as u_i^l , $(l, i) \in \mathcal{A} \cup \mathcal{R}$, is unknown to Bob, we have a maximum value of K + R that satisfies the reliability condition. Then, R should be determined under the security condition constraints. Since imposing high BER at Eve does not guarantee any information theoretic security, we adopt the leakage-based security condition instead of the BER-based security condition suggested in [9]. The information leakage can be estimated by the Tal-Vardy construction with the upgrading approximation and the parameter $\mu = 64$ for polar codes, which offers an upper bound on the capacity of polarized bit-channels [32]. Thus, the normalized information leakage is calculated by

$$L_k^E = \frac{1}{K} \sum_{(l,i)\in\mathcal{A}} C\left(W_{2,N}^{l(i)}\right) \tag{45}$$

where $C(W_{2,N}^{l(i)})$ is the estimated capacity of the *i*-th polarized bit-channel at the *l*-th bit-level of Eve's channel. Note that as Rincreases, L_k^E will decrease due to the selection method of \mathcal{R} in the following paragraph. We choose R to be the minimum value such that the security condition is satisfied for efficient and secure transmission. However, if the value of K is forcibly given, we may need to sacrifice some security to obtain an R. Now, the desired input distribution is set as the optimized input distribution P_{X^*} resulting in a mutual information I(X;Y)equal to (K+R)/N for fixed $\text{SNR}_B-\text{SNR}_E = d\text{SNR}_g$ across SNR_B . Thus, we choose the value of D to be $\kappa_D(q-H(X))$, where κ_D is a scaling factor for better shaping performance [42]. Finally, F is calculated as F = qN - K - R - D.

The index sets \mathcal{F} , \mathcal{A} , \mathcal{R} , and \mathcal{D} are selected according to the sort of $H(U_i^l|V_i^l)$, $H(U_i^l|V_i^l, Y)$ and $H(U_i^l|V_i^l, Z)$. We can use the Monte-Carlo approach to estimate these entropies. To estimate $H(U_i^l|V_i^l)$, we perform the MSD with SC decoding similar to that used in the encoder, that is, the SC decoder at each bit-level is initialized with a priori LLRs. By choosing u_i^l successively with the randomized rounding rule (42) for all $l \in [\![q]\!]$ and $i \in [\![N]\!]$, the decoder successively outputs $P_{U_i^l|\mathbf{V}_i^l}(\cdot|\mathbf{v}_i^l)$. After many trials, we obtain the estimates of $H(U_i^l|V_i^l)$. As for the estimates of $H(U_i^l|V_i^l, Y)$, we repeat the transmission over the channel, where the transmitter sends randomly generated data and the receivers perform an MSD with SC decoding. When the SC decoder makes a wrong decision on u_i^l , we count the number of errors at this bit position and correct the error before moving to the next bit position. After sampling over enough frames, we calculate the error rate ε_i^l for each bit position. Since $H\left(U_i^l|V_i^l,Y\right)$ is a monotonically increasing function of ε_i^l , the sort of $H\left(U_{i}^{l}|\textbf{V}_{i}^{l},\textbf{Y}\right)$ is equivalent to the sort of ε_{i}^{l} for all bit positions. Finally, the estimate of $H\left(U_i^l|V_i^l, Z\right)$ is the same as that of $H\left(U_{i}^{l}|\mathbf{V}_{i}^{l},\mathbf{Y}\right)$.

Now, the F bit positions with the highest $H\left(U_i^l|V_i^l,Y\right)$ are

Fig. 6. Eve's BER P_e^E and the estimated normalized information leakage L_k^E versus $\text{SNR}_B - \text{SNR}_E$ for different modulation and message length K over the Gaussian wiretap channel, where $L_{k,\text{max}}^E = 0.2$, $P_{e,\text{max}}^B = 10^{-5}$, and N = 1024.

selected into the index set \mathcal{F} and the D bit positions with the lowest $H\left(U_i^l|V_i^l\right)$ are selected into the index set \mathcal{D} . Among the remaining positions, the R bit positions with the lowest $H\left(U_i^l|V_i^l, \mathbf{Z}\right)$ form the index set \mathcal{R} and the remains form the index set \mathcal{A} .

We also remark that if the polar codes are constructed for AWGN channel, one can follow the idea of binary-input AWGN surrogates proposed in [43] and perform the Tal-Vardy construction [32] or Gaussian approximation construction [44] on each bit-level to estimate the entropies with less amount of computation. Moreover, if we construct for Rayleigh fading (RF) channel, the RF channel can be equivalent to an AWGN channel with the same ergodic average achievable rate as the RF channel [45]. Thus, the polar construction for RF channel is transformed to the construction for AWGN channel.

C. Complexity Analysis

The encoding and decoding procedures of the proposed coding scheme leverage conventional MSD and SCL decoding, without the need for any additional operations. At the *l*-th bit-level, the encoder first traverses 2^{q-l+1} channel inputs x for each possible bit label $b^{[l-1]}$ to calculate the probability $P_{B^l|B^{[l-1]}}(\cdot|b^{[l-1]})$, followed by an SCL decoder with list size L_e . Thus, the overall encoding complexity can be represented as $\mathcal{O}(q(Q + L_e N \log_2(N)))$. As for decoding, a maximum a posteriori (MAP) demapper, which needs to traverses 2^{q-l+1} channel inputs x for N channel observations y at the *l*-th bit-level, and an SCL decoder with list size L_d are performed. The resulting decoding complexity is $\mathcal{O}(qN(2^{q-l+1} + L_d \log_2(N)))$.

VI. SIMULATION RESULTS

In this section, we evaluate the performance of the proposed scheme with Monte-Carlo simulations. In the following simulations, we perform the Tal-Vardy construction [32] with the degrading approximation and the parameter $\mu = 32$ for polar construction. Let SNR_B^* and SNR_E^* be the SNR points for Bob and Eve at which we acquire the desired input

Fig. 7. The maximum achievable message length K for Q-ASK input over the Gaussian wiretap channel under constraints of $S_g = 3$ dB, $P_{e,\max}^B = 10^{-5}$, and $L_{k,\max}^E = 0.2$, where $Q \in \{4, 8, 16\}$ and N = 1024.

distribution in Sec. V-B. The design SNRs for estimating $H(U_i^l|V_i^l, Y)$ and $H(U_i^l|V_i^l, Z)$ are chosen to be SNR_B^* and SNR_E^* , respectively. At both the encoder and the decoder, we use an SCL decoder of list size $L_e = 16$ and $L_d = 16$, respectively. An 8-bit cyclic redundancy check (CRC) code is attached at the end of the message as an outer code. The shaping bits are determined according to the argmax rule (43). We set κ_D to be 1.15 for 4-ASK, 1.1 for 8-ASK, and 1.05 for 16-ASK.

Please note that many wiretap coding schemes [9]–[13], especially coded modulation schemes [17], [18], are designed for BER-based security. However, a high BER at Eve can not necessarily derive a low leakage I(M; Z) considered in our work, and it is difficult to estimate the information leakage for these codes themselves and their application to coded modulation systems. For a fair comparison, we extend the polar wiretap codes [8] to high-order modulation by directly applying the MLC construction as a baseline. This scheme, referred to as the uniform case hereafter, is in fact a special case of the proposed coding scheme when $\mathcal{D} = \emptyset$, and can

Fig. 8. The achievable normalized rate-equivocation pairs for 8-ASK input over the Gaussian wiretap channel, where $P_{e,\max}^B = 10^{-5}$, $\text{SNR}_B = 13$ dB, and $\text{SNR}_E = 10$ dB.

Fig. 9. The achievable normalized rate-equivocation pairs for 16-ASK input over the Gaussian wiretap channel, where $P_{e,\max}^B = 10^{-5}$, $\text{SNR}_B = 18$ dB, and $\text{SNR}_E = 13$ dB.

be easily proved to achieve the secrecy rate of DMWC with uniform constellation input.

Fig. 6 illustrates the curves of Eve's BER P_e^E and the estimated normalized information leakage L_k^E as SNR_B – SNR_E increases for different transmission parameters over the Gaussian wiretap channel. The coding parameters are obtained according to $d\text{SNR}_B = \text{SNR}_B$, $d\text{SNR}_g$ given in the figure, the security threshold $L_{k,\text{max}}^E = 0.2$, and the reliability threshold $P_{e,\max}^B = 10^{-5}$. It can be observed that the proposed shaped scheme achieves higher P_e^E and lower L_k^E at eavesdropper compared to the uniform case, that is, achieves more secure communication. The security gap S_g is calculated by (9) and also presented in Fig. 6. The results show that the proposed scheme achieves at least 0.6 dB gain on S_g . Furthermore, we observe that our leakage-based security condition ensures that Eve's BER P_e^E is close to 0.5, while the BER-based security condition, with a typical value of $P_{e,\min}^E = 0.49$ for the security threshold [9]-[13], causes a normalized information leakage even larger than 0.6. This indicates that the estimated information leakage is a more stringent security metric than

Fig. 10. The estimated leakage L_k^E as a function of N, where $P_{e,\max}^B = 10^{-5}$. For 8-ASK, $SNR_B = 13$ dB and $SNR_B = 10$ dB, while for 16-ASK, $SNR_B = 18$ dB and $SNR_B = 13$ dB.

the BER in terms of wiretap channel codes design.

If a security gap $S_g = 3$ dB with the reliability threshold $P_{e,\max}^B = 10^{-5}$ and the security threshold $L_{k,\max}^E = 0.2$ is required, we find the maximum achievable message length K for 4-ASK, 8-ASK, and 16-ASK input at different SNR_B by numerical simulations with dSNR_B = SNR_B and dSNR_g = S_g . The results are illustrated in Fig. 7. We observe that the shaped scheme always obtains a higher value of K across SNR_B and modulation order Q. That is to say, under the same requirements on the reliability performance and security performance, the proposed shaped scheme is more bandwidth efficient than the uniform input case.

To further reveal the relationship between transmission efficiency and security, we present the normalized rateequivocation pairs (R_t, \bar{R}_e) achieved by the proposed shaped scheme and the uniform scheme at finite block length regimes, where the equivocation rate R_e is normalized to $\bar{R}_e = R_e/R_t$ for better illustration. Note that since \bar{R}_e can be expressed in the form of information leakage, i.e., $\bar{R}_e = H(M|Z)/K =$ $1 - I(\boldsymbol{M}; \boldsymbol{Z})/K$, we can use the estimated normalized information leakage L_k^E to compute \bar{R}_e . Now, Figs. 8 and 9 depict the achievable normalized rate-equivocation pairs for 8-ASK and 16-ASK inputs with a reliability threshold $P_{e,\max}^B = 10^{-5}$ and different block length, respectively. The boundary of the achievable rate-equivocation region defined by (8) is also provided. We observe that there is a trade-off between transmission efficiency and security, that is, a higher transmission rate R_t will cause a less normalized equivocation rate \bar{R}_e , indicating a higher risk of information leakage. Nevertheless, the curve generated by the pairs (R_t, \overline{R}_e) with the same N of the proposed shaped scheme always lies above the one obtained by the uniform scheme, which means that the proposed scheme is more bandwidth efficient and secure than the uniform input case. Specifically, the proposed scheme enables higher transmission rate when satisfying the same security condition, or equivalently, the proposed scheme achieves more secure transmission when satisfying the same reliability condition and transmission rate.

Fig. 11. Eve's BER P_e^E and the estimated normalized information leakage L_k^E versus $\text{SNR}_B - \text{SNR}_E$ for different modulation orders and message length K over the RF wiretap channel, where $L_{k,\max}^E = 0.2$, $P_{e,\max}^B = 10^{-4}$ and N = 1024.

Moreover, as the block length N increases, Figs. 8 and 9 show that the pairs (R_t, \bar{R}_e) asymptotically approach the boundary of the achievable rate-equivocation region (i.e., the limits for $N \to \infty$). In Fig. 10, we further show the estimated leakage L_k^E as a function of N for a given transmission rate, which indicates that the information leakage caused by our shaped scheme is obviously lower than the one of the uniform scheme, and tends to zero as $N \to \infty$. This also verifies that the proposed scheme satisfies the weak security condition, as proved in Theorem 3.

In addition, we assess the performance of our scheme over the RF wiretap channel, where the gains of Bob's channel and Eve's channel follow the i.i.d. complex Gaussian distribution with zero-mean and unit variance, respectively. We assume that Bob and Eve know their respective channel state information perfectly. Fig. 11 illustrates Eve's BER P_e^E and the estimated leakage L_k^E as $\text{SNR}_B - \text{SNR}_E$ increases over the RF wiretap channel, which presents analogous performance to that observed over the Gaussian wiretap channel. If we choose the reliability threshold $P_{e,\max}^B = 10^{-4}$ and the security threshold $L_{k,\max}^E = 0.2$, the security gap S_g is also provided in Fig. 11. We observe that fading brings a great challenge to secure transmission, reflected in the significant increase of the security gap. This is mainly because, due to the impact of fading, the instantaneous SNR of Eve's channel may be superior to that of Bob's channel, which leads to the direct exposure of message to Eve. Nevertheless, the proposed shaped scheme still achieves a gain over 0.65 dB on security gap S_q compared to the uniform input case.

Finally, we evaluate the impact of the list sizes for encoding and decoding on the security performance, as shown in Table I. Other simulation parameters except the list sizes are the same as that in Fig. 6(a). Since L_e and L_d affect the shaping and decoding performance, respectively, an increase in S_g is observed as they decrease. Nonetheless, the security gap S_g is less sensitive to L_e compared to L_d . The results tell us that there is a trade-off between the complexity and the security performance of the proposed scheme, and we need to determine the list sizes according to practical requirements.

TABLE I IMPACT OF ENCODING LIST SIZE L_e and Decoding List Size L_d on the Security Gap S_q

Le	L_d	S_g	
C	u	Shaped	Uniform
16	16	3.90 dB	454 dD
8	16	3.91 dB	4.54 ub
8	8	3.99 dB	4.70 dB
4	8	4.00 dB	
4	4	4.19 dB	4 04 dB
2	4	4.22 dB	4.74 UD

VII. CONCLUSION

In this work, we have performed PS in the wiretap channel model. Under the constraints of Gaussian wiretap channel with ASK/QAM constellation input, we have found a sub-optimal solution to the input distribution optimization problem that maximizes the achievable secrecy rate R_s . The resulting suboptimal solution P_{X^*} can still lead to an R_s close to the Gaussian secrecy capacity. In order to achieve secure communication with shaped input, we have proposed a probabilistic shaped multilevel polar coding scheme. Specifically, for the asymmetric DMWC with constellation input, we have proven that the bit-channels of multilevel polar codes will polarize into four sets \mathcal{F} , \mathcal{A} , \mathcal{R} and \mathcal{D} , and proposed to fill the bit positions indexed by these four sets with frozen bits, message bits, random bits and shaping bits, respectively. Such polar codes are proven to achieve the secrecy capacity of asymmetric DMWC, while satisfying the reliability condition and the weak security condition. The above conclusions also hold for the Gaussian wiretap channel. Moreover, the coding procedure and security-oriented construction method of proposed multilevel polar codes for finite block length have been provided.

Numerical results have shown that the proposed scheme can achieve a more secure and bandwidth efficient transmission than the uniform input case over the Gaussian wiretap channel, that is, at least 0.6 dB gain on the security gap S_g or significant improvement on the message length K. As block length N tends to infinity, it has been verified that the proposed scheme satisfies the weak security condition. Furthermore, the proposed scheme also outperforms the uniform scheme over the RF wiretap channel on the security gap. Future research may consider the shaped coded modulation scheme satisfying the strong security condition. Also, the security performance over the fading wiretap channel may be further improved by integrating with multiple-input multiple-output, precoding and other technologies.

APPENDIX A Proof of Lemma 1

By the definition of channel degradation, we know that there exists a DMC \tilde{W} such that $W_2(z|x) = \sum_y W_1(y|x) \tilde{W}(z|y)$. By (11) and invertibility of $f(\cdot)$, we have $P_{Z|B}(z|b) = \sum_y P_{Y|B}(y|b) P_{Z|Y}(z|y)$. Since the bit-levels are independent of each other, we further have

$$W_{2}^{l}\left(z, \boldsymbol{b}^{\llbracket l-1 \rrbracket} | b^{l}\right) = P_{Z, \boldsymbol{B}^{\llbracket l-1 \rrbracket} | B^{l}}\left(z, \boldsymbol{b}^{\llbracket l-1 \rrbracket} | b^{l}\right)$$

$$= \sum_{\boldsymbol{b}^{\llbracket q \rrbracket \setminus \llbracket l \rrbracket}} P_{Z, \boldsymbol{B}^{\llbracket l-1 \rrbracket} | \boldsymbol{B}^{\llbracket q \rrbracket \setminus \llbracket l-1 \rrbracket}}\left(z, \boldsymbol{b}^{\llbracket l-1 \rrbracket} | \boldsymbol{b}^{\llbracket q \rrbracket \setminus \llbracket l-1 \rrbracket}\right)$$

$$= \sum_{\boldsymbol{b}^{\llbracket q \rrbracket \setminus \llbracket l \rrbracket}} P_{\boldsymbol{B}^{\llbracket l-1 \rrbracket} | \boldsymbol{B}^{\llbracket q \rrbracket \setminus \llbracket l-1 \rrbracket}}\left(\boldsymbol{b}^{\llbracket l-1 \rrbracket} | \boldsymbol{b}^{\llbracket q \rrbracket \setminus \llbracket l-1 \rrbracket}\right)$$

$$\cdot P_{Z|\boldsymbol{B}}\left(z | \boldsymbol{b}\right) \qquad (46)$$

$$= \sum_{\boldsymbol{y}} \sum_{\boldsymbol{b}^{\llbracket q \rrbracket \setminus \llbracket l \rrbracket}} P_{\boldsymbol{B}^{\llbracket l-1 \rrbracket} | \boldsymbol{B}^{\llbracket q \rrbracket \setminus \llbracket l-1 \rrbracket}}\left(\boldsymbol{b}^{\llbracket l-1 \rrbracket} | \boldsymbol{b}^{\llbracket q \rrbracket \setminus \llbracket l-1 \rrbracket}\right)$$

$$\cdot P_{Y|\boldsymbol{B}}\left(y | \boldsymbol{b}\right) P_{Z|Y}\left(z | y\right)$$

$$= \sum_{\boldsymbol{y}} W_{1}^{l}\left(y, \boldsymbol{b}^{\llbracket l-1 \rrbracket} | b^{l}\right) \tilde{W}\left(z | y\right).$$

Thus, we have $W_2^l \preceq W_1^l$.

APPENDIX B Proof of Lemma 3

Let V = (S, Y) and T = (S, Z). Then, we have $Z_B (U_i | S, Z)$ $\stackrel{(a)}{=} 2 \sum_t \sqrt{P_{U_i,T}(0,t) P_{U_i,T}(1,t)}$ $\stackrel{(b)}{=} 2 \sum_t \sqrt{P_{U_i}(0) P_{T|U_i}(t|0) P_{U_i}(1) P_{T|U_i}(t|1)}$ $\stackrel{(c)}{=} 2 \sum_t \sqrt{\sum_v P_{U_i}(0) P_{V|U_i}(v|0) P_{T|V}(t|v)}$ $\cdot \sqrt{\sum_v P_{U_i}(1) P_{V|U_i}(v|1) P_{T|V}(t|v)}$ $\stackrel{(d)}{\geq} 2 \sum_t \sum_v \sqrt{P_{U_i}(0) P_{V|U_i}(v|1) P_{T|V}(t|v)}$ $\cdot \sqrt{P_{U_i}(1) P_{V|U_i}(v|1) P_{T|V}(t|v)}$ (47)

$$= 2 \sum_{\boldsymbol{v}} \sqrt{P_{U_i,\boldsymbol{V}}(0,\boldsymbol{v}) P_{U_i,\boldsymbol{V}}(1,\boldsymbol{v})} \sum_{\boldsymbol{t}} P_{\boldsymbol{T}|\boldsymbol{V}}(\boldsymbol{t}|\boldsymbol{v})$$
$$= Z_B(U_i|\boldsymbol{S},\boldsymbol{Y}).$$

The equalities (a) and (b) are immediate from the definition of Bhattacharyya parameter and conditional probability, respectively. By the definition of channel degradation, there exists a DMC \tilde{W} such that $\bar{W}_{2,N}(t|u) = \sum_{v} \bar{W}_{1,N}(v|u) \tilde{W}(t|v)$. Combined with (11), the equality (c) holds. Finally, the inequality (d) follows from the Cauchy-Schwartz inequality.

APPENDIX C PROOF OF PROPOSITION 1

For each bitlevel $l \in \llbracket q \rrbracket$, consider the sets

$$\mathcal{L}_{B^{l}} = \left\{ (l,i) : Z_{B} \left(U_{i}^{l} | \mathbf{V}_{i}^{l} \right) < \delta_{N} \right\},$$
(48)

$$\mathcal{H}_{B^{l}} = \left\{ (l,i) : Z_{B} \left(U_{l}^{l} | \boldsymbol{V}_{l}^{l} \right) > 1 - \delta_{N} \right\}, \tag{49}$$

$$\mathcal{L}_{B^{l}|Y} = \left\{ (l,i) : Z_{B} \left(U_{i}^{l} | \boldsymbol{V}_{i}^{l}, \boldsymbol{Y} \right) < \delta_{N} \right\},$$
(50)

$$\mathcal{H}_{B^{l}|Y} = \left\{ (l,i) : Z_{B} \left(U_{i}^{l} | \boldsymbol{V}_{i}^{l}, \boldsymbol{Y} \right) > 1 - \delta_{N} \right\}.$$
(51)

By [27, Lem. 1], we have

$$1 - \lim_{N \to \infty} \frac{|\mathcal{L}_{B^l}|}{N} = \lim_{N \to \infty} \frac{|\mathcal{H}_{B^l}|}{N} = H(B^l | \boldsymbol{B}^{[l-1]})$$
(52)

$$1 - \lim_{N \to \infty} \frac{\left| \mathcal{L}_{B^{l} | Y} \right|}{N} = \lim_{N \to \infty} \frac{\left| \mathcal{H}_{B^{l} | Y} \right|}{N} = H(B^{l} | \boldsymbol{B}^{\llbracket l - 1 \rrbracket}, Y).$$
(53)

Note that, for $l \neq k$, $\mathcal{L}_{B^l} \cap \mathcal{L}_{B^k} = \mathcal{H}_{B^l} \cap \mathcal{H}_{B^k} = \mathcal{L}_{B^l|Y} \cap \mathcal{L}_{B^k|Y} = \mathcal{H}_{B^l|Y} \cap \mathcal{H}_{B^k|Y} = \emptyset$ by definition. Thus

$$\mathcal{L}_{X} = \bigcup_{l \in \llbracket q \rrbracket} \mathcal{L}_{B^{l}}, \quad \mathcal{L}_{X|Y} = \bigcup_{l \in \llbracket q \rrbracket} \mathcal{L}_{B^{l}|Y},$$

$$\mathcal{H}_{X} = \bigcup_{l \in \llbracket q \rrbracket} \mathcal{H}_{B^{l}}, \quad \mathcal{H}_{X|Y} = \bigcup_{l \in \llbracket q \rrbracket} \mathcal{H}_{B^{l}|Y}.$$
(54)

Since $f(\cdot)$ is invertible, we have

$$\lim_{N \to \infty} \frac{1}{N} |\mathcal{L}_X| = \lim_{N \to \infty} \frac{1}{N} \sum_{l \in \llbracket q \rrbracket} |\mathcal{L}_{B^l}|$$
$$= \sum_{l \in \llbracket q \rrbracket} 1 - H(B^l | \mathbf{B}^{\llbracket l - 1 \rrbracket}) \qquad (55)$$
$$= q - H(X).$$

The proofs of the remaining equalities in (26) and (27) follow analogously to (55).

APPENDIX D Proof of Theorem 1

By (27), we immediately have

$$\lim_{N \to \infty} \frac{|\mathcal{F}|}{N} = q - \lim_{N \to \infty} \frac{|\mathcal{L}_{X|Y}|}{N} = H(X|Y).$$
(56)

From (26), we know that $\lim_{N\to\infty} (\mathcal{H}_X \cup \mathcal{L}_X)^C = \emptyset$. By the fact that $\mathcal{L}_X \subseteq \mathcal{L}_{X|Z} \subseteq \mathcal{L}_{X|Y}$, we have

$$\lim_{N \to \infty} \frac{|\mathcal{D}|}{N} = \lim_{N \to \infty} \frac{\left|\mathcal{L}_{X|Y} \cap (\mathcal{L}_X \cup (\mathcal{H}_X \cup \mathcal{L}_X)^C)\right|}{N}$$
$$= \lim_{N \to \infty} \frac{\left|\mathcal{L}_{X|Y} \cap \mathcal{L}_X\right|}{N}$$
$$= q - H(X).$$
(57)

Additionally, from (27), we have

$$\lim_{N \to \infty} \frac{|\mathcal{A}|}{N} = \lim_{N \to \infty} \frac{\left| (\mathcal{L}_{X|Y} \setminus \mathcal{L}_{X|Z}) \cap (\mathcal{L}_X \cup (\mathcal{H}_X \cup \mathcal{L}_X)^C) \right|}{N}$$
$$= \lim_{N \to \infty} \frac{\left| (\mathcal{L}_{X|Y} \setminus \mathcal{L}_{X|Z}) \cap \mathcal{L}_X \right|}{N}$$
$$= \lim_{N \to \infty} \frac{\left| \mathcal{L}_{X|Y} \right| - \left| \mathcal{L}_{X|Z} \right|}{N}$$
$$= (q - H(X|Y)) - (q - H(X|Z))$$
$$= I(X;Y) - I(X;Z)$$
(58)

and

$$\lim_{N \to \infty} \frac{|\mathcal{R}|}{N} = \lim_{N \to \infty} \frac{|\mathcal{L}_{X|Z} \setminus (\mathcal{L}_X \cup (\mathcal{H}_X \cup \mathcal{L}_X)^C)|}{N}$$
$$= \lim_{N \to \infty} \frac{|\mathcal{L}_{X|Z} \setminus \mathcal{L}_X|}{N}$$
$$= (q - H(X|Z)) - (q - H(X))$$
$$= I(X; Z).$$
(59)

APPENDIX E Proof of Lemma 4

Suppose that Eve knows the realization u_A of U_A and wants to estimate U_R with SC decoding. Thus, Eve can treat both U_F and U_A as frozen bits. Since $\mathcal{R} = \mathcal{L}_{X|Z} \cap \mathcal{H}_X$, it is precisely the scenario considered in [27]. By [27, Theorem 2], the error probability of Eve's estimate \hat{U}_R is given by

$$\lambda \stackrel{\text{def}}{=} \Pr\{\hat{\boldsymbol{U}}_{\mathcal{R}} \neq \boldsymbol{U}_{\mathcal{R}}\} \le c2^{-N^{\beta'}} \tag{60}$$

for any $0 < \beta' < \beta < 1/2$. Let $\mathcal{U}_{\mathcal{R}}$ be the alphabet of $\mathcal{U}_{\mathcal{R}}$. Since $\mathcal{U}_{\mathcal{R}}$ is uniform over $\{0,1\}^{|\mathcal{R}|}$, the size of $\mathcal{U}_{\mathcal{R}}$ is $2^{|\mathcal{R}|}$. Using Fano's inequality [46, Theorem 2.10.1], we bound the conditional entropy $H(\mathcal{U}_{\mathcal{R}}|\mathcal{Z},\mathcal{U}_{\mathcal{A}})$ as follows

$$H(\boldsymbol{U}_{\mathcal{R}}|\boldsymbol{Z},\boldsymbol{U}_{\mathcal{A}}) \leq h_{2}(\lambda) + \lambda \log(|\boldsymbol{\mathcal{U}}_{\mathcal{R}}|)$$

$$\stackrel{(a)}{\leq} h_{2}(c2^{-N^{\beta'}}) + c|\mathcal{R}|2^{-N^{\beta'}}$$
(61)

where (a) holds from (60), $|\mathcal{U}_{\mathcal{R}}| = 2^{|\mathcal{R}|}$, and the fact that the binary entropy function $h_2(\cdot)$ is an increasing function on the interval [0, 1/2].

APPENDIX F Proof of Theorem 3

The information leakage I(M; Z) is upper bounded by

$$I(\boldsymbol{M};\boldsymbol{Z}) \stackrel{(a)}{=} I(\boldsymbol{U}_{\mathcal{A}};\boldsymbol{Z})$$
$$\stackrel{(b)}{=} I(\boldsymbol{U}_{\mathcal{A}\cup\mathcal{F}};\boldsymbol{Z})$$

$$= I(\boldsymbol{U}; \boldsymbol{Z}) - I(\boldsymbol{U}_{\mathcal{R}}; \boldsymbol{Z} | \boldsymbol{U}_{\mathcal{A} \cup \mathcal{F}}) - I(\boldsymbol{U}_{\mathcal{D}}; \boldsymbol{Z} | \boldsymbol{U}_{\mathcal{A} \cup \mathcal{F} \cup \mathcal{R}}) \stackrel{(d)}{=} I(\boldsymbol{U}; \boldsymbol{Z}) - I(\boldsymbol{U}_{\mathcal{R}}; \boldsymbol{Z} | \boldsymbol{U}_{\mathcal{A} \cup \mathcal{F}})$$
(62)
$$\stackrel{(e)}{=} I(\boldsymbol{U}; \boldsymbol{Z}) - H(\boldsymbol{U}_{\mathcal{R}} | \boldsymbol{U}_{\mathcal{A}}) + H(\boldsymbol{U}_{\mathcal{R}} | \boldsymbol{Z}, \boldsymbol{U}_{\mathcal{A}}) \stackrel{(f)}{=} I(\boldsymbol{U}; \boldsymbol{Z}) - |\mathcal{R}| + H(\boldsymbol{U}_{\mathcal{R}} | \boldsymbol{Z}, \boldsymbol{U}_{\mathcal{A}}) \stackrel{(g)}{\leq} NI(X; \boldsymbol{Z}) - |\mathcal{R}| + H(\boldsymbol{U}_{\mathcal{R}} | \boldsymbol{Z}, \boldsymbol{U}_{\mathcal{A}}) \stackrel{(h)}{\leq} NI(X; \boldsymbol{Z}) - |\mathcal{R}| + h_2(c2^{-N^{\beta'}}) + c|\mathcal{R}|2^{-N^{\beta'}}.$$

The equalities (a) and (b) follow from $U_{\mathcal{A}} = M$ and $U_{\mathcal{F}} = 0$, respectively. Since the sets \mathcal{F} , \mathcal{A} , \mathcal{R} , \mathcal{D} are disjoint and $\mathcal{F} \cup \mathcal{A} \cup \mathcal{R} \cup \mathcal{D} = \{(l, i) : l \in [\![q]\!], i \in [\![N]\!]\}$, (c) holds by the chain rule of mutual information. Note that $U_{\mathcal{D}}$ is deterministic given $U_{\mathcal{A} \cup \mathcal{F} \cup \mathcal{R}}$. Hence, $I(U_{\mathcal{D}}; \mathbf{Z} | U_{\mathcal{A} \cup \mathcal{F} \cup \mathcal{R}}) = 0$ and (d) holds. The equality (e) follows from $U_{\mathcal{F}} = \mathbf{0}$ and the definition of conditional mutual information. Since $U_{\mathcal{R}}$ and $U_{\mathcal{A}}$ are independent, and $U_{\mathcal{R}}$ is a priori uniform over $\{0, 1\}^{|\mathcal{R}|}$, we obtain the equality (f). Inequality (g) follows from the fact that U is encoded to X, and then X is transmitted over Nindependent uses of W_2 , where the achievable rate of W_2 is upper bound by I(X; Z) for a given input distribution P_X . Finally, (h) is immediate from Lemma 4.

Dividing both sides of (62) by N, we have

(c)

$$\frac{I(\boldsymbol{M};\boldsymbol{Z})}{N} = I(X;Z) - \frac{|\mathcal{R}|}{N} + \frac{h_2(c2^{-N^{\beta'}})}{N} + \frac{c|\mathcal{R}|}{N} 2^{-N^{\beta'}}.$$
(63)

As $N \to \infty$, it is obvious that the last two terms in (63) tend to 0 since $|\mathcal{R}| = \Theta(N)$. Moreover, we have $\lim_{N\to\infty} I(X;Z) - |\mathcal{R}|/N = 0$ by (35). Thus, we complete the proof of the theorem.
